Department of Pathology, B.J. Medical College, Ahmedabad, Gujrat, India

Abstract: Infertility is one of the major problems in developed as well as many developing countries. About fifteen percent of all marriages face the problem of infertility. A study of semen analysis and testicular biopsy was done in 80 infertile males. History of smoking was encountered in 29 (34.12%) cases, 56 (70%) patients were clinically normal in terms of tests and scrotum. Varicocele (41.67%) was the most common positive clinical finding responsible for infertility. Though the specific reason for infertility is unknown, it was the most common abnormal histopathological finding (18.75%), followed by maturation arrest, testicular atrophy and granulomatous inflammation of testis (11.25% each). On semen analysis, 71.25% cases had azoospermia, 24.71% cases had oligospermia and 2.35% cases had normal sperm count. Oligospermia is usually associated with inflammatory etiology. Among oligospermics and normospermics, the sperm motility was more than 50% in 14 patients (60.67%). Among the azoospermic patients, 35.09% showed normal spermatogenesis in their testicular biopsy. Although azoospermia is commonly associated with normal spermatogenesis, it is a hallmark of spermatogenic arrest. Thus, testicular biopsy is invaluable in the azoospermics but its usefulness is limited in the oligospermics.

Keywords: Azoospermia, Oligospermia, Sertoli cell only syndrome (SCOS)

INTRODUCTION
Infertility is empirically defined as the inability of a couple to conceive after one year of coital activity without contraception.1 Since the burden of a childless marriage is borne by the female, it was a gynecologist who attempted the first exploratory measures for the diagnosis of infertility in male.2 The statistics of infertility show that about 15 to 20 percent of the marriages (every 7th couple) face the problem of infertility in the developed countries.1 In the developing countries the prevalence is variable, it is as high as 30% in Sub Saharan Africa to as low as 5% in China.3 Males alone are responsible for almost 30% of all cases and in another 20% both the partners have detectable abnormalities.4 The ever increasing interest in the study of male infertility has stimulated the investigation of spermatogenic physiology, semen abnormality and the pituitary gonadal relationship and the microscopic study of the testicular tissue, making a bewildering array of diagnostic options available. The most basic and simple screening test for evaluation still remains the semen analysis and testicular biopsy. Semen analysis is relatively inexpensive and can provide valuable information if done correctly.5,6

MATERIAL AND METHOD
The present study was conducted in the department of pathology over a period of 2 years, starting from January 2005 to December 2006. This study is based upon the histopathological examination of the testicular biopsies. The biopsies were obtained from 80 infertile males with abnormal semen examination. The age of incidence was from 20 to 45 years. Cases for testicular biopsy were selected after taking detailed clinical history, thorough clinical examination and semen analysis. The detailed clinical history including age, the duration of active marriage life, duration of infertility, sexual relationship, frequency of coitus, premature ejaculation, psychological status and libido was noted. History regarding alcohol consumption, smoking and other substance abuse was also inquired into. Occupational exposure to radiation, heat and pesticides was asked. Past history of infection like mumps, measles, pneumonia, sexually transmitted diseases (STD), tuberculosis and any surgical procedure was also asked. Secondary sex characters and genital organs examination was done. The systemic examination to exclude anemia, tuberculosis, diabetes mellitus was also carried out. Clinical diagnosis was confirmed by ultrasonography whenever necessary.

Semen analysis was done in all the patients and parameters like total sperm count, motility and presence or absence of abnormal forms were looked into. Before collection, the patients were advised for three days of abstinence. Semen samples were collected in the laboratory room in a clean, dry, biologically inert container. In case of oligospermic or azoospermic patients, three semen samples were collected on alternate days and thorough examination was carried out. Spermatozoa were counted using the hemocytometer chamber under high power in all four WBC squares using semen diluting fluid consisting of sodium bicarbonate and formalin in distilled water18,20 (1:20 dilution). The sperm counting was carried out same as WBC counting. Sperm count is one of the most useful tests for evaluation of fertility in men. As the name implies a semen specimen containing no spermatozoa on at least two examinations is said to be azoospermic. Before stamping azoospermic, the sample must be centrifuged and check the pellet for sperms. The count in oligospermia may range from very few spermatozoa to 20 million. To evaluate the motility, a small drop of liquefied semen was placed on a prewarmed slide, covered with a cover slip and was seen under high power. Smear must be prepared from pellet and stained with leishman stain to check the sperm morphology.20 It is usually found that lower the count, higher the number of abnormal forms. Cases were categorized into three groups i.e. group I with azoospermia, group II with oligospermia (count <20 million / ml) and group III with normal count. According to motility they are divided in 4 grades.

1 Grade a (fast progressive) sperms are those which swim forward fast in a straight line-like guided missiles
2 Grade b (slow progressive) sperms swim forward but either in a curved or crooked line, slowly/slow linear/non linear
3 Grade c (non progressive) sperms move their tails, but do not move forward
4 Grade d (immotile) sperms do not move at all.

Sperms of grade c and d motility are considered of poor quality. Testicular biopsy was done in all the azoospermics, oligospermics and normospermics with relevant clinical history. The testicular biopsy specimens were taken by urologist after proper cleaning of scrotum with an antiseptic solution, and the area around it is covered with sterile cloth. A local anesthetic was injected into the skin of the scrotum. Then a small incision was made through the skin, and a tiny piece of testicular tissue was removed using “Window’s microsurgical technique”.20 Approximately 3 mm size specimen was excised using “No touch technique” and placed in Bouin’s fixative. A single stitch was used to close the incision in the testicle and another stitch is used to close the incision in the skin with an

unabsorbable sutures. The scrotal area was then bandaged and patient was informed to wear an athletic support for several days after the procedure. The biopsy took approximately 15-20 minutes. Patient had been advised to refrain from sexual activity for 1 to 2 weeks after biopsy and avoid washing the area for several days. After fixation the tissue was processed and paraffin embedded. Sections were cut and stained with haematoxylin and eosin stain. Special staining for elastic fibers, collagen and crystals of reinke were done wherever indicated. In the interpretation of testicular biopsy, attention was paid to the size, shape and population density of seminiferous tubules, the state of basement membrane, various stages of spermatogenesis and components of the interstitial tissue. Some degree of subjectivity does occur in the interpretation of mild hypospermatogenesis and tubular hypoplasia, since there are no clear guidelines for the range of normality. In the present study, testicular biopsy was reported individually by two different pathologists to reduce the subjectivity.

RESULTS

Eighty (80) patients of male infertility between the periods from January 2005 to December 2006 were selected on the basis of semen examination. Patients with azoospermia, oligospermia and normospermia were selected for biopsy.

As table 1 shows, the age group of 25 – 35 years is the most common age group, 56 out of the selected 80 patients (app. 69.70 %) fall in this age group and after the age of 35 years, the number of cases significantly decreased. History of smoking was present in 29 (34.12 %) cases.

Table 2 shows that the majority of the patients, 56 out of 80 (70 %) were clinically normal. Clinically positive findings were found only in 24 patients. Out of these 24 patients, 10 (41.67 %) had varicocele. Thus varicocele was the most common positive clinical finding encountered, followed by hernia, cryptorchidism and small testes (16.67 % each). Out of all 80 cases, only 1 case of hernia and 2 cases of small testes were bilateral.

Table 5: Correlation of Histopathological Examination

During semen analysis 68 (80%) cases had normal semen volume. Out of the selected 80 patients of infertility, 57 (71.25%) were azoospermic, 21 (24.71%) were oligospermic and 2 (2.35%) were normospermic. Thus, azoospermia was the most common finding in semen analysis. Table 4 shows that among the 23 patients (normospermic and oligospermic) studied for sperm motility, irrespective of the sperm count, 14 cases (60.87 %) had motility more than grade III and average motility was 50-76.

DISCUSSION

At the current level of advancement using the multidisciplinary approach involving the pathologist, gynecologist and the urologist, improvement in the quality of the ejaculate can be attained in a reasonably large percentage of men, provided that the diagnostic and prognostic measures available are used to their fullest extent. The semen analysis must be considered as the most important investigation in the evaluation of an infertile male. Increase in the scrotal temperature due to tight wearing of the underwear and/or other causes also give variation in the sperm count. Robinson and associates cooled the scrotum of euspermic and oligospermic men with ice bag for 30 minutes daily for 2 weeks. A transient increase in the sperm concentration by about 3 folds was noted. Testicular biopsy is being re-evaluated as a step in the investigation of male infertility. With the advent of micromanipulation techniques in the field of fertility management, now even a single viable sperm can be used to fertilize an ovum. Testicular biopsy has gained therapeutic importance also. As the name implies, testicular biopsy consists of an operative removal of a small bit of tissue from the testes, small enough to have no deleterious effects on the normal functioning of the gland, yet large enough to include a representative sample of the whole gland.

In the present study, the most common age group affected was 25 – 35 years comprising around 70 % of the cases. Similar finding (76 %) was
achieved by Trupti et al in 2004. In the present study, 25 % of the patients were below 25 years, whereas Trupti et al found only 8 % of the patients in this age group. This is due to early age of marriage in India. Proper history taking and clinical examination is also important as it is known that smoking decreases the sperm density as well as sperm motility, and to a lesser extent it cause an increase in the number of morphologically abnormal sperms. History of smoking was noticed in 29 (34.12 %) patients.

Regarding the clinical examination of testes, 70.77 % (56 out of 80) of patients, who had normal sized testes, had abnormality in the semen examination. Trupti et al found 35 out of 50 (70 %) were clinically normal with no symptoms, and had abnormalities in semen examination. Thus, the results are comparable. Though they were clinically normal they had azoospermia in semen examination and/or germ cell aplasia in histopathological examination. This occurs because we can clinically see only the size of testes or secondary sex characters. Although thorough semen examination was done, until and unless biopsy was done, we could not reach the proper conclusion.

The histological lesion associated with varicocele was hypospermatogenesis, which was similar to the changes reported by other workers. Fertility is reversible after curing this condition. Varicocele affects the function of testes in two ways. Firstly, chronic venous congestion leading to hypo spermatogenesis and atrophy of testes and secondly, the inhibitory effect of this raised scrotal temperature on sperms along with abnormal testicular hormonal environment due to regurgitation.

Cryptorchidism was found in 5 % of the cases. The contralateral testes also had mild changes of atrophy in them, although clinically normal. In cases of cryptorchidism, it is important to perform orchidopexy before the age of puberty; otherwise an atrophic change start to appear in the contralateral testis also and also leads to a higher risk of bilateral malignancy.

The present study shows 71.25 % of the cases (57 out of 80 patients) were azoospermic and 35.00 % of the azoospermia were associated with normal spermatogenesis. Similar finding were obtained by Trupti et al and Ahmad et al, while Kurien et al found 50 % of the patients had normal spermatogenesis on fine needle aspiration cytology examination. These findings suggest that the obstructive etiology is one of the major causes responsible for male infertility and has a good prognosis. The obstruction may occur at the level of epididymis or vas deferens. In case of obstructive azoospermia followed by maturation arrest and sertoli cell only syndrome (SCOS) (7.5 % each). Whatever the histopathological finding, fertility in these non obstructive cases is not reversible. In case of obstruction at the level of vas deference, the semen volume is low (0.5 ml or less), fructose is absent and the pH is acidic. The non obstructive azoospermia is commonly associated with maturation arrest, sertoli cell only syndrome (SCOS) and testicular atrophy. Similar findings were reported by Trupti et al. Ahmad et al found testicular atrophy (35 % of the cases) was the major cause of non obstructive azoospermia followed by maturation arrest and sertoli cell only syndrome (SCOS) (7.5 % each). Fertility in these non obstructive cases is not reversible.

The present study shows 24.71 % of cases (21 out of 80 patients) were oligospermic, while Trupti et al found 46 % (23 out of 50 patients) were oligospermic. Oligozoospermia was primarily associated with normal spermatogenesis and inflammatory lesions. Though semen analysis is an important screening test for evaluation, there are discrepancies in selecting cases for testicular biopsy on the basis of sperm count. We have taken sperm count of 20 million/ml as a cut off point for oligospermia and normospermia. Among all oligospermics and normospermics, mean motility was 50-70 % in 14 cases. Results are comparable to Trupti et al.

Azoospermia, is a common finding in both, normal spermatogenesis which is suggestive of obstruction and has a good prognosis and also in potentially bad prognostic lesions like sertoli cell only syndrome (SCOS) and maturation arrest. Azoospermia can be due to obstructive or non obstructive lesions. Some authors advocate biopsy to distinguish the type of azoospermia while others advocate quantitative methods. Biopsy is useful to evaluate spermatogenesis as well as for prognosis. On biopsy, normal histology suggests either partial or complete obstruction or possibility of antisperm antibodies. Regarding the findings of a testicular biopsy for the evaluation of male infertility number of studies are available. Trupti et al observed hypospermatogenesis as a common lesion, while Ahmad et al found testicular atrophy (35 %) as a major cause responsible for male infertility followed by sertoli cell only syndrome (SCOS) and maturation arrest (7.5 % each) Kurien et al found maturation arrest and testicular atrophy as a common finding (12.7 %) followed by sertoli cell only syndrome (SCOS) (3.6 %). We reported sertoli cell only syndrome (SCOS) as the most common lesion (18.75 %) followed by maturation arrest and testicular atrophy (11.25 % each) and the fertility potentialpathological finding, fertility is not reversible in these cases and so, prognosis is poor. Out of 80 patients studied in this series, the best prognosis can be predicted for the patients having normal histology or obstructive lesions. The worst prognosis is predicted in sertoli cell only syndrome (SCOS), maturation arrest at primary spermatocytes level and testicular atrophy.

CONCLUSIONS

• Smoking decreases the sperm density, sperm motility and cause morphologically abnormal sperms. History of smoking was encountered in 34.12 % cases.

• Varicocele (41.67 %) was the most common positive clinical finding and it was associated with normal spermatogenesis.

• Maturation arrest, sertoli cell only syndrome (SCOS), and testicular atrophy were exclusively associated with azoospermia.

• Of all the cases studied, the diagnosis suggestive of obstruction was made in 36 % of the cases. Non obstructive pathology was found in 64 % of the cases.

• In the 80 cases studied, the best prognosis was found in the lesion ‘suggestive of obstruction’ and bad prognosis was found in sertoli cell only syndrome and maturation arrest.

• semen analysis and testicular biopsy provide valuable information about the etiology and the fertility potential of an individual.

• Testicular biopsy is invaluable in the azoospermics but its usefulness is limited in the oligospermics.

• Histological examination of the testis gives a correct assessment of the spermatogenesis and allows a rational choice for the future management by reconstructive surgery, hormonal therapy, artificial donor insemination or adoption.

Male factor infertility is involved in approximately 50% of infertile couples, and in 30% of the cases, an abnormality is discovered solely in the man.2 Despite the enormity of these numbers, the medical treatment of male infertility is continually frustrating, in light of the numerous etiologies but few which are truly amenable to effective medical management. Badenoch and colleagues,9 in a study comparing the sperm density of 104 proven fertile men with 51 infertile men, found that 11.5% of the fertile men had sperm densities of less than 20 million/mL, and 33% of the infertile population had sperm densities greater than 20 million/mL. A testicular biopsy can be used to diagnose lumps, causes of infertility, and obtain sperm for in vitro fertilization. There are several types of biopsies. A testicular biopsy takes a tissue sample from your testicle for laboratory analysis. The two testicles are the male reproductive organs. They produce sperm and the male sex hormone testosterone. Your testicles are located in your scrotum, which is the fleshy pouch of tissue that hangs under your penis. A testicular biopsy can be used to: diagnose the location and condition of a lump in the testes. diagnose causes of male infertility. obtain sperm for in vitro fertilization (IVF). There are two different procedures for a testicular biopsy.
